## ABSTRACT

This study was an attempt to map the density field in a fin-flat plate junction three-dimensionally using holographic interferometry. This investigation has extended the density studies by Matulka [12, 13] and Jagota [3, 4] to include, for the first time, interferometric fringe information obtained through a transparent model in supersonic flow. The fringe information was then inverted by a FORTRAN computer program to produce a plot of the density field around the model. The feasibility of the method was demonstrated.

The factors which are thought to have limited the success of the experiment include vibration of the model, fluctuations of the tunnel flow and the fact that the model was somewhat too large in relation to the size of the wind tunnel test section. Schlieren photography was used to look through and around the model and to verify that the same flow was established as was reported by Thomas [23, 24] and Winkelmann [26, 27].

The data reduction of holographic interferograms was, for the first time, accomplished using photographic enlargements. This technique is considered to be much easier and more accurate than the one used in the previous investigations. However, the data reduction step, because of the time and labor involved, is considered to be the rate controlling process of the whole analysis.

#### ACKNOWLEDGEMENTS

This writer wishes to gratefully acknowledge Dr. D. J. Collins for his most valuable guidance and assistance during the course of this investigation; Dr. T. H. Gawain for his valuable assistance and recommendations in the writing of this report; the technical staff of the Department of Aeronautics under R. Besel and T. Dunton, particularly N. Lechenby, J. Multon, and G. Middleton, for their able assistance in the fabrication and assembly of the models and equipment used in this study; Mrs. John B. Coleman Jr. for her considerable effort in the final preparation; and my wife and family for their noble patience and encouragement.

## I. INTRODUCTION

The determination of the flow field in the wing-body junction of an aircraft in supersonic flight presents many problems. The typical approach has been to measure the static pressure on the surface using many small pressure taps [23, 24] and to determine the velocity field in the junction using translatable pressure probes [18, 19, 25]. Thomas [24] and Winkelmann [26, 27] used azobenzene and oil-smear tests to view the flow field around a flat plate-fin junction. From the streak patterns on the plate and fin, they were able to illustrate the three-dimensional flow field, although in a partially speculative fashion. This study has attempted to map the density field in a fin-flat plate junction three dimensionally using holographic interferometry. Although this objective was not fully achieved, the feasibility of the method has been demonstrated.

By using a Q-switched laser with exposure times of about twenty nanoseconds, it was possible to obtain three-dimensional holographic interferograms of the density field in the fin-flat plate junction. From holograms taken at a number of viewing angles the fringe shifts in different planes could be obtained. By integrating this information using a FORTRAN computer program, the density field can be determined. This technique has been previously demonstrated for the flow field of a free jet by Matulka [12, 13] and for the supersonic flow field around a cone at angle of attack by Jagota [3, 4].

The tests were performed at the Naval Postgraduate School, using the four-inch supersonic wind tunnel.

## II. EXPERIMENTAL APPARATUS

### A. THE WIND TUNNEL

The investigation was conducted in the Naval Postgraduate School blowdown-to-atmosphere supersonic wind tunnel. The test section is four inches by four inches in cross section and six inches long with two different sets of side walls. The two-inch thick plexiglas side walls, which have a refraction index of 1.49, present a complete field of view of the flow from the nozzle throat to aft of the test section mounting bracket (Figure 1 (a)). The second set of sidewalls used are aluminum with high quality optical glass portholes located in the test section area (Figure 1 (b)). The interchangeable nozzle for a test section Mach number of 2.8 was used for all tests. The nominal run time is five minutes at Mach 2.8 with the maximum stagnation pressure of about 105 pounds per square inch.

### B. THE HOLOGRAPHIC ARRANGEMENT

The holographic arrangement is illustrated in Figure 2 and shown in photographs included as Figures 3, 4, and 5. The equipment stand was rested on a portion of the building floor that was vibrationally isolated. A Konrad K-1 pulsed ruby laser with a Pockels cell Q-switching unit was used to produce monochromatic light at a wave length of 6943 Angstroms and exposure time of twenty nano-seconds. The laser cavity length was seventy-three cm. giving a coherence length of about ten cm. To maintain the laser head and output etalon at a constant temperature of 27.5 degrees centigrade, a Lauda constant temperature circulator Model N was used. This was controlled by an electronic relay type R-10 coupled with a Culligan de-ionizer.

Holograms were obtained by routing the reference beam under the wind tunnel and the scene beam through the test section, and intersecting the two beams on the hologram plate at an intersecting angle of approximately 50 degrees. The beam sizes were controlled by translating the concave lenses located between the beam splitter and hologram plate in each beam (Figure 2). The Q-switched laser and optics were aligned using a continuous wave helium-neon laser. For reference purposes, grids were mounted on the outside tunnel walls and aligned using a surveyor's transit. The holographic stand and test section were completely enclosed in a wooden box to enable holograms to be taken in the daylight (Figure 6).

#### C. THE WIND TUNNEL MODELS

The fin-flat plate models used are shown in Figures 7 (a), (b), (c), and (d). The metal portions of both models were stainless steel. The center section, part of one strake, and all of the other strake of the first model in Figure 7 (a) were made of epoxy while the center section of the second model, Figures 7 (b) and 7 (c), was fabricated from plexiglas. The flat plate grids in both models were etched into the plastic surface and coated with a clear plastic to achieve a smooth surface.

The models were rotated about their sting mounts as shown in Figure 7 (d). Alignment for the desired rotation angle was accomplished by aligning prescribed lines on the sting mount collar with a scribed mark on the sting stand using a surveyor's transit.

### III. ANALYTICAL EVALUATION OF THE DENSITY FIELD

#### A. THE BASIC INTERFEROMETRIC EQUATION

Interferograms are created when two coherent light beams are superimposed on each other and projected on a viewing screen. The light and dark regions observed correspond to the relative phase difference between the two beams which are caused by a difference in the two optical path lengths. Consider a coherent beam which is split and then recombined on a viewing screen. A difference in optical path lengths of the two beams may be achieved in two ways in order to create an interferogram. The first is to make the physical distance traveled by the two beams different. In a vacuum this path length difference is expressed as  $L = C_0 \Delta t$  where  $C_0$  is the speed of light in a vacuum. The second way is to maintain equal physical path lengths but to have the beams traverse through different media prior to recombining. In this case each light beam will travel at a speed  $\frac{C_0}{n}$  where  $n$  is the index of refraction for the medium traversed. The optical path length difference then becomes:

$$\Delta L = L (n_2 - n_1) = C_0 \Delta t \quad (1)$$

The interference pattern or fringes observed may be expressed as a function of the optical path length difference or

$$g = \frac{\Delta L}{\lambda} \quad (2)$$

where:

$g$  = fringe shift

$\lambda$  = wave length of the light source

$\Delta L$  = change in optical path

Combining equations (1) and (2), the fringe shift is then

$$g = \frac{L}{\lambda} (n_2 - n_1) \quad (3)$$

The index of refraction is known to be a function of density. Since the speed of light is only slightly less in gases than in a vacuum, the index of refraction could be closely approximated by the series expansion [8]

$$n = 1 + \beta \frac{\rho}{\rho_s} \quad (4)$$

where

$\beta$  = dimensionless constant related to the Gladstone-Dale  
constant by  $K = \beta/\rho_s$

$\rho_s$  = reference density of 0° C, 760 mm. Hg.

The variation of with wavelength is small and has a value of 0.000292 for  $\lambda = 5893$  angstroms.

Considering a fixed difference in the index of refraction between the two beams in Equation (3), then

$$g = \beta \frac{L}{\lambda} \left( \frac{\rho_2 - \rho_\infty}{\rho_s} \right) \quad (5)$$

If the density varies in a beam path, the net change in the optical path length will be the integrated effect along the beam path or

$$g = \frac{\beta}{\lambda \rho_s} \int_0^L (\rho - \rho_\infty) ds = Q \int_0^L f(x, y, z_c) ds \quad (6)$$

where

$$Q = \frac{\beta \rho_\infty}{\lambda \rho_s} \quad (6a)$$

$$f(x, y, z_c) = \frac{\rho(x, y, z_c)}{\rho_\infty} - 1 \quad (6b)$$

$z_c$  = a plane of constant  $z$

$ds$  = incremental distance along the ray

In order to determine the density along the beam path where the fringe shift is known from an interferogram, Equation (6) must be inverted.

#### B. THE INTEGRAL INVERSION

The integral inversion technique was first reported by C. D. Maldonado et al in 1965 [9, 10, 11]. R.D. Matulka [12, 13] and R. C. Jagota [3, 4] used this method to determine the density variation in an asymmetric free jet and about a cone at angle of attack, respectively. The technique involves representing the function,  $f(x, y, z)$  in Equation (6) by a complete set of orthogonal functions where the unknown coefficients are evaluated using the orthogonality relationship between the set of functions. The functions are orthogonal over the entire plane and also have the property of being invariant in form to any rotation of the coordinate system. Figure 8 illustrates the coordinate system for the inversion where  $x$  and  $y$  are the fixed laboratory coordinates and  $x'$  and  $y'$  are the coordinates in which the fringe number function is defined. As the view through the test section is varied the primed coordinates are rotated with respect to the fixed coordinates  $x$  and  $y$ .

The fringe shift expressed in Equation (6) may be written as the transform

$$g(\xi, y, z_c) = f(x, y, z_c) \quad (7)$$

or, inverting the equation, the density function,  $f$ , is equal to:

$$f(x, y, z_c) = T^{-1} g(\xi, y, z_c) \quad (8)$$

The density function can be expanded in the following manner using a set of polynomial functions,  $U_{m+2k}^{\pm m}(\alpha x, \alpha y)$ , and unknown complex coefficients,  $C_{m+2k}^{\pm m}(\alpha)$

$$f(x, y, z_c) = \sum_{m=0}^{\infty} \sum_{k=0}^{\infty} \epsilon_m [C_{m+2k}^m(\alpha) U_{m+2k}^m(\alpha x, \alpha y) + C_{m+2k}^{-m}(\alpha) U_{m+2k}^{-m}(\alpha x, \alpha y)] \cdot e^{-(\alpha^2 x^2 + \alpha^2 y^2)} \quad (9)$$

where: 
$$\epsilon_m = \begin{cases} 1/2 & m=0 \\ 1 & m=1, 2, 3, \dots \end{cases}$$

$\alpha$  = arbitrary scale factor

The polynomial functions,  $U_{m+2k}^{\pm m}(\alpha x, \alpha y)$ , are invariant in form to a rotation of the coordinate system [10, 12, 13]. They also have a Gauss transform which makes them adaptable to the physical situation and to manipulating into the form of Equation (7). The functions are defined as:

$$U_{m+2k}^{\pm m}(\alpha x, \alpha y) = (-1)^k \alpha \left[ \frac{k! (\alpha^2 x^2 + \alpha^2 y^2)^m}{\pi (m+k)!} \right]^{1/2} e^{\pm i m \phi} L_k^m(\alpha^2 x^2 + \alpha^2 y^2) \quad (10)$$

where  $\phi = \tan^{-1}\left(\frac{y}{x}\right) - \frac{\pi}{2}$  (10a)

$L_k^m$  = Laguerre polynomial

$$= \sum_{s=0}^k \left[ \frac{(m+k)!}{(k-s)!(m-s)!s!} \right] [(-1)^s (\alpha^2 x^2 + \alpha^2 y^2)]^s \quad (10b)$$

And the Gauss Transform of  $U_{m+2k}^{\pm m}$  is:

$$I_{m+2k}^{\pm m}(\alpha y; \xi) = \int_{-\infty}^{\infty} U_{m+2k}^{\pm m}(\alpha x, \alpha y) e^{-\alpha^2 x'^2} dx' = \frac{e^{\pm i m \xi} H_{m+2k}(\alpha y')}{[k! (m+k)!]^{1/2} 2^{m+2k}} \quad (11)$$

where  $H_{m+2k}(\alpha y)$  = Hermite polynomials

By applying the transform above to Equation (9), the fringe function in

Equation (7) can be written as:

$$g(\xi, y, z_c) = \sum_{m=0}^{\infty} \sum_{k=0}^{\infty} \frac{c_m [C_{m+2k}^{(1)}(\alpha) e^{im\xi} + C_{m+2k}^{(2)}(\alpha) e^{-im\xi}] H_{m+2k}(\alpha) e^{-\alpha^2 y^2}}{[k!(m+k)! 2^{2(m+k)}]^{1/2}} \quad (12)$$

using the following orthogonality relationship on Equation (12)

$$\int_{-\pi}^{\pi} e^{im\xi} e^{-in\xi} d\xi \int_{-\infty}^{\infty} H_{m+2k}(\alpha y') H_{n+2l}(\alpha y') e^{-\alpha^2 y'^2} dy' = \frac{2\pi^{3/2}}{\alpha} [(m+2k)!(n+2l)! 2^{m+2k} 2^{n+2l} \delta_{mn} \delta_{(m+2k)(n+2l)}] \quad (13)$$

where  $\delta$  is the kroneker delta, the expansion coefficients  $C_{m+2k}^{(1)}$ , can be determined by:

$$C_{m+2k}^{(1)}(\alpha) = \frac{\alpha}{2\pi^{3/2}} \left[ \frac{(k!(m+k)!)^{1/2}}{(m+2k)!} \right] \int_{-\pi}^{\pi} g(y', \xi, z_c) H_{m+2k}(\alpha y') e^{-im\xi} dy' d\xi \quad (14)$$

Substitution of the coefficients in Equation (14) back into Equation

(9) results in the density variation being expressed as:

$$f(x, y, z_c) = \left(\frac{\alpha}{\pi}\right)^2 \sum_{m=0}^{\infty} \sum_{k=0}^{\infty} c_m [k!(m+k)!]^{1/2} e^{-(\alpha^2 x^2 + \alpha^2 y^2)} \cdot \text{REAL} \left[ \int_{-\pi}^{\pi} \int_{-\infty}^{\infty} g(y', \xi, z_c) e^{-im\xi} H_{m+2k}(\alpha y') dy' d\xi \right] U_{m+2k}^m(\alpha x, \alpha y) \quad (15)$$

or by inserting Equation (10):

$$f(x, y, z_c) = \left(\frac{\alpha}{\pi}\right)^2 \sum_{m=0}^{\infty} \sum_{k=0}^{\infty} c_m \frac{(1)^k k!}{(m+2k)!} (\alpha^2 x^2 + \alpha^2 y^2)^{m/2} L_k^m(\alpha^2 x^2 + \alpha^2 y^2) \cdot [B_{m+2k}^m(\alpha) \cos(m\phi) + D_{m+2k}^m(\alpha) \sin(m\phi)] e^{-(\alpha^2 x^2 + \alpha^2 y^2)} \quad (16)$$

where:

$$B_{m+2k}^m(\alpha) = \int_{-\pi}^{\pi} \int_{-\infty}^{\infty} g(y', \xi, z_c) \cos(m\xi) H_{m+2k}(\alpha y') dy' d\xi \quad (17)$$

$$D_{m+2k}^m(\alpha) = \int_{-\pi}^{\pi} \int_{-\infty}^{\infty} g(y', \xi, z_c) \sin(m\xi) H_{m+2k}(\alpha y') dy' d\xi \quad (18)$$

Equations (16), (17), and (18) are the basic equations used to calculate the density distribution from the experimentally determined fringe variations.

### C. THE NUMERICAL PROCEDURE

The form of the density distribution in Equations (16), (17), and (18) must be modified in order to input the experimentally determined fringe distribution. First from Figure 8 and Equation (6b) it can be seen that it is only necessary to integrate Equations (17) and (18) over an area where the density is changing from a known density,  $\rho_\infty$ . Outside of this region where there is no change in density, the function  $f(x, y, z) = 0$ , i.e. outside the test section. Also since the fringe distribution is taken in small increments over the test area the coefficients, B and D, can be approximated as

$$B_{m+2k}^m(\alpha) = \sum_{i=1}^{I-1} \sum_{j=0}^{J-1} g(\xi_j + \Delta\xi_j, x_i + \Delta x_i) \int_{\xi_j}^{\xi_{j+1}} \cos(m\xi) d\xi \int_{x_i}^{x_{i+1}} H_{m+2k}(\alpha x) dx \quad (19)$$

$$D_{m+2k}^m(\alpha) = \sum_{i=1}^{I-1} \sum_{j=0}^{J-1} g(\xi_j + \Delta\xi_j, x_i + \Delta x_i) \int_{\xi_j}^{\xi_{j+1}} \sin(m\xi) d\xi \int_{x_i}^{x_{i+1}} H_{m+2k}(\alpha x) dx \quad (20)$$

The integral of  $\xi$  is easily determined and by using the derivative formula for Hermite polynomials the integral of  $x$  may be manipulated to yield

$$B_{m+2k}^m(\alpha) = \left[ \frac{1}{2\alpha m(m+2k+1)} \right] \sum_{i=0}^{I-1} \sum_{j=0}^{J-1} g(\xi_j + \Delta\xi_j, x_i + \Delta x_i) \cdot [\sin(m\xi_{j+1}) - \sin(m\xi_j)] [H_{m+2k+1}(\alpha x_{i+1}) - H_{m+2k+1}(\alpha x_i)] \quad (21)$$

$$D_{m+2k}^m(\alpha) = - \left[ \frac{1}{2\alpha m(m+2k+1)} \right] \sum_{i=0}^{I-1} \sum_{j=0}^{J-1} g(\xi_j + \Delta\xi_j, x_i + \Delta x_i) \cdot [\cos(m\xi_{j+1}) - \cos(m\xi_j)] [H_{m+2k+1}(\alpha x_{i+1}) - H_{m+2k+1}(\alpha x_i)] \quad (22)$$

In the computation of the density function from Equation (16), obtaining the infinite summations experimentally is not plausible or

possible. It has been demonstrated that by using a finite number of terms and by adjusting the values of  $\Delta \xi$ ,  $\Delta x$  and  $\alpha$ , it is possible to obtain the density distribution with very good accuracy [3, 4, 12, 13]. Equation (16) then becomes:

$$\begin{aligned} f(x, y, z) = & \left(\frac{\alpha}{\pi}\right)^2 \sum_{k=0}^K \sum_{m=0}^M \epsilon_m (-1)^k \left[ \frac{k!}{(m+2k)!} \right] (\alpha^2 x^2 + \alpha^2 y^2) \cdot \\ & L_k^m(\alpha^2 x^2 + \alpha^2 y^2) \left[ B_{m+2k}^m(\alpha) \cos(m\phi) + D_{m+2k}^m(\alpha) \sin(m\phi) \right] \cdot \\ & e^{-(\alpha^2 x^2 + \alpha^2 y^2)} \end{aligned} \quad (23)$$

#### IV. EXPERIMENTAL PROCEDURE

##### A. LABORATORY TECHNIQUES

The analysis of a free jet by Matulka [12, 13] illustrated how holographic interferometry can be used to obtain a complete three dimensional plot of the density within a moving transparent flow field. Jagota [3, 4] in his study of a cone at angle of attack in supersonic flow went one step further by introducing an opaque object into an assumed steady state flow field and describing the density field three-dimensionally.

This investigation has attempted to determine the three-dimensional density field around a transparent object in a supersonic flow field by passing a light beam through the object. Specifically the interest was to describe the flow field existing in the junction of a fin-root intersection.

##### 1. Model Considerations

In order to obtain uniform flow around the fin-root area, a model of the form shown in Figure 9 was selected. The flat plate has a knife

edge and is intended to remain at zero degrees angle of attack so as to establish the flow conditions illustrated. The fin edges were made circular in order to approach flow conditions similar to those established in Winkelmann's [26, 27] investigation. Plastic and metal strakes were added on the model sides so as to maintain two-dimensional flow as well as to add strength to the flat plate. In the first model constructed (Figure 7(a)), maximum visibility of the plastic fin-flat plate center section was achieved by bolting the leading edge and aft plate together through the plastic center section. Due to model flexure, this design was found to be unsuitable and the second model in Figures 7(b) and 7(c) was constructed. The model was made from a single piece of stainless steel. The model rigidity was satisfactory but unfortunately the strengthening borders around the plastic center section reduced the holographic visibility somewhat.

Since the wind tunnel blocks were fixed, it was possible to make multiple test runs with the same flow conditions over the model provided supersonic flow had been established over the model.

## 2. Holographic Techniques

In order to obtain holographic interferograms it was necessary to ensure that the optical path lengths of the scene and reference beams remained approximately equal. Since the ruby laser is believed to have a coherence length of approximately ten centimeters, the quality of lengths is far less critical than in the classical Mach-Zehner interferometric approach. Consequently a string was used in the experiment to trace the reference beam and then adjust the scene beam. This method kept the two beam lengths within one centimeter of each other. Since the scene beam traversed approximately 4.5 inches of plastic tunnel walls and

grids which the reference beam did not, it was necessary to compensate by making the scene beam physically 2.25 inches shorter than the reference beam. The reference beam varied in length from 61 inches to 68 inches during the experimentation.

To determine the fringe/density field, finite fringe interferograms were made by three different techniques. In the direct fin-root flow approach the diffuser plate was part of the model. Either the mirror,  $M_5$ , in Figure 2 or the hologram plate holder was translated between the no-flow exposure and the flow-established exposure. In the total model flow method the diffuser plate was located between scene beam lens,  $L_3$ , and the test section (See Figure 2) and it was translated horizontally or vertically. Translations were varied from .001 inches to .006 inches with the translation distance of .003 inches yielding the best fringe separation.

Most of the holograms taken using basically the holographic arrangement shown in Figure 2 gave well-defined fringe patterns. In order to improve upon the fringe definition, a variety of techniques was attempted. The transverse mode selector was varied from 1.0 mm. to 2.5 mm. in increments of 0.5 mm. to determine the best lighting of the model. The hologram plate holder was rotated horizontally to various positions. These positions varied between being perpendicular to the scene beam to being perpendicular to the bisection of the angle between the scene and reference beams. Polarization plates were added in both the scene and reference beams between the test section and hologram plate in the scene beam and between the last mirror,  $M_4$ , and the hologram plate in the reference beam. A one-quarter wave plate was also placed between the first lens,  $L_1$ , and the beam splitter as recommended by Okayama and Emori [14].

The holograms were taken using 4" x 5" Agfa-Gavaert 8E-75 hologram plates. The developing process involved:

1. Five minutes in Kodak D-19 developer
  2. Thirty seconds in an acetic acid stop bath
  3. Five minutes in standard fixer
  4. Five minutes in a flowing water bath
  5. One minute emersion in Kodak Photo Flo wetting agent
  6. Drying using blowing cool air
- a. Direct Fin-Root Flow Method

Since the flow field in the fin-root junction is assumed to be identical on either side of the fin, then it is only necessary to determine the density on one side of the fin. To accomplish this it is necessary to obtain holograms for  $180^\circ$  of view as shown in Figure 10. The holograms for the views from  $0^\circ$  to  $90^\circ$  can be obtained by using a frosted fin and flat plate as shown in Figure 11. The advantage of having the frosted plate as part of the model is that the fringe/density information obtained by the interferogram is believed to be only for the area between the fin-root intersection to the tunnel wall vice the whole test section, but this was not verified. In order to obtain the fringe information for angles greater than  $90^\circ$  but less than  $180^\circ$  the fin would be exchanged for one containing a stainless steel reflective surface. The scene beam would then enter the test area from the viewing port below the tunnel and be reflected to the hologram plate as shown in Figure 12.

b. Total Model Flow Method

In this method the diffuser plate was located in the scene beam outside the test section as shown in Figure 14 and the flat plate

center section and fin were made of optically clear plexiglas. By translating the diffuser plate between exposures of the hologram, an interferogram of the whole density field in the test section about the model was obtained. From Figure 13 it can be seen that due to symmetry only  $90^\circ$  of view was required to obtain the density field. This makes it much easier experimentally to take the holograms than the previous method described.

### 3. Schlieren Analysis

A standard Schlieren knife-edge system was used to verify the establishment of the supersonic flow network around the model as shown in Figure 9. Photographs were also taken of the flow with the model at  $0^\circ$  and  $90^\circ$  rotation in order to compare the fin shock conditions with those obtained by Winkelmann [26, 27].

### B. PHOTOGRAPHIC TECHNIQUES

By illuminating the holograms with a helium-neon laser beam which has a wave length of 6328 Angstroms, the original scene was reconstructed. Since the original scene beam and the reconstructed beam were of different wave lengths, there is actually a small distortion in the reconstructed scene but of neglectable effect because the hologram plate emulsion in the development process also shrinks.

The typical method for reconstructing the scene is to illuminate the hologram as illustrated in Figure 15. The diffuse glass used in the construction of the hologram appears to act as an infinite light source of non-parallel rays which illuminates the scene. If a small aperture is positioned at the focal plane of the imaging lense, an almost parallel set of rays may then be selected as shown in Figure 16. A third method

illustrated in Figure 17 uses a small diameter conjugate beam to illuminate the hologram. A large depth of field is achieved because the narrow beam acts as an aperture. This effect was of considerable advantage since it enabled both the front and rear grids, the model, and the fringe patterns to be simultaneously projected on the screen. The best photographs were obtained by focusing on the plane of the fringes.

### C. DATA REDUCTION

Photographic interferograms were obtained by illuminating the hologram scene with a thin laser beam and using a camera with a viewing screen located in the film plane as shown in Figure 15. The line of sight in the plane desired was achieved by translating the hologram until common points on the front and rear grids were aligned. The camera, with the aperture set wide open at  $f/7.7$ , was then adjusted to give the best focus on the fringe plane. The best photographic results were achieved by using an exposure time of  $1/10$  second with Polaroid Type 55 P/N film.

It was felt that the density field could be well defined three-dimensionally along the fin if the density fields were determined in four planes perpendicular to the  $Z$ -axis and equally spaced along the fin as shown in Figure 18. In obtaining the fringe data across a constant  $Z$ -plane it would be necessary to take six photographs per rotation angle, aligned at appropriate intervals down the  $y'$  axis, and then graphically mate the fringe data to form one complete set. The six photos across the field were felt necessary because the optical path length from the model to the hologram plate varied for those points not on the aligned plane.

The fringe shift reduction was accomplished using two different techniques. The first was to project the negative, using a photo enlarger,

onto a sheet of paper and trace out the fringe pattern, model surfaces and grid lines. The light fringes were traced out since it was much easier to judge their center line. From the fringe lines forward of the fin in the region of uniform flow one fringe line which appeared the straightest and compatible with most others was selected as the bench mark. A straight line was then drawn over that fringe and extended past the aligned Z plane (i.e.  $y'$  axis). Lines parallel to the bench mark line were then drawn likewise over the remaining fringe lines. The fringe displacements were then read relative to the lines drawn at the points of intersection of the fringes with the  $y'$  axis. The radius of the inversion circle was selected so that the fin-root intersection was the origin and the fin tip was the 100 percent point.

In the second technique an enlarged positive photograph was made from the negative. Again one fringe line in the uniform flow region just forward of the fin which appeared to be parallel with the majority of the fringes was selected as the bench mark. The remaining fringes were likewise traced over with lines parallel to the first. The fringe displacements were then measured relative to the lines drawn. For further details see Appendix A.

The locations at which reference lines crossed the  $y'$  axis in both techniques above were further adjusted to account for the tunnel wall refraction displacement as shown in Figure 19 and computed by a computer program in Appendix B. Once these corrections were made, the radial variation of the fringe number could then be plotted for the various  $y'$  alignment planes and a smooth curve drawn through the data points. The fringe number at 201 equidistant points across the field can then be obtained for input into the computer program, HOLOFER, in MODE 3. For

further details on how to use the computer program, HOLOFER, see Appendix C. Once the data from all the rotation angles of the model have been put into the computer program, the program will then calculate the density field across the inversion circle for that Z-plane. After the density has been calculated for all four Z-planes in Figure 18, a three-dimensional plot of the density field can be made by connecting points of equal density across the fin.

## V. EXPERIMENTAL RESULTS AND DISCUSSION

The initial attempts to establish uniform flow over the flat plate shown in Figure 7(a) were unsuccessful due to model vibration and flexure. Movement of the model sting within its holder and flexure of the model plastic center section allowed the model leading edge to establish a little over  $1^\circ$  angle of attack upward when flow was established. Due to various modifications made in attempts to eliminate the vibration, the sting finally fractured.

In an attempt to eliminate these problems, the second model shown in Figures 7(b) and 7(c) was made of a single piece of stainless steel and the sting was mated to its holder to within .001 inches. The model center section was made of poured epoxy and the strakes were both made of stainless steel with plexiglas inserts. The model rotation about the sting was reduced to approximately  $0.3^\circ$  angle of attack upward. Due to the vibration in passing through the transonic range and a weak glue seal between the metal strakes and plexiglas inserts, the inserts were found to break loose. They were subsequently removed and not replaced.

In order to determine the flow field using the direct fin-root approach, the epoxy fin and model center section were frosted on one side using fine

emery paper (see Figure 20). Holograms were taken of the model at rotation angles of  $0^\circ$ ,  $12^\circ$ ,  $45^\circ$  and  $90^\circ$  using the holographic arrangement in Figure 2 excluding the diffuser plate between lens,  $L_3$ , and the test section. The mirror,  $M_5$ , was translated in various directions from towards to parallel to the test section between the exposures without flow and with flow established. Fringe patterns were obtained around the model, but only at  $0^\circ$  and  $12^\circ$  rotation could any fringe patterns be observed across the fin. It was found that the fin fringe pattern appeared to remain almost unchanged no matter how or how much the mirror,  $M_5$ , was translated while the fringe around the model changed appropriately. For instance, in Figure 21 the mirror was not translated and in Figure 22 the mirror was translated .006 inches horizontally parallel to the tunnel.

Since fringes could not be observed across the flat plate at  $45^\circ$  and  $90^\circ$ , it was felt that the epoxy center section might be too imperfect optically. Consequently double-exposed holograms were taken with no flow through the test section and various translation distances from 0 to .005 inches. The fringe patterns were excellent across the whole model and their spacing decreased according to the increase in the translation of  $M_5$ . Next the diffuser plate in the scene beam in Figure 2 was inserted with the model at  $0^\circ$  rotation angle and translated between no flow and flow exposures of the hologram. The fringes about the model were of excellent quality but the double diffusion of the scene beam through the model caused all fringe patterns on the model (fin) to disappear.

It was felt at this point that the fringe pattern obtained across the fin was caused by the movement of the model to an angle of attack and possibly by model vibration, although none was observed visually. The

lack of any fringes across the flat plate center section is not well understood but is believed to be caused by vibration of the model.

Since it was not possible to obtain acceptable interferograms with the diffuser plate as part of the model due to model motion, it was felt that the effect of minor model movements could be eliminated by using an optically clear model and an external translating diffuser plate. Therefore the fin and model center sections were replaced with optically clear plexiglas. With these changes it was found that the flat-plate leading-edge angle of attack had been reduced to approximately  $0.1^\circ$ .

Initially double-exposure holograms were taken using the arrangement in Figure 2 and translating the diffuser horizontally. At  $0^\circ$  model rotation the holographic interferograms were excellent. But as observed in Figure 23 it would be extremely difficult to determine the fringe change across the fin since no free stream reference fringes were available, due to the flat plate leading edge Prandtl-Meyer expansion and fin shock intersecting the tunnel top just above the fin. With a larger tunnel or smaller model this would be an excellent technique.

The diffuser plate was then translated vertically between exposures and excellent horizontal fringe patterns were obtained as shown in Figure 24. The model was then rotated to  $22\frac{1}{2}^\circ$  and the same holographic technique was used. Excellent fringe patterns were obtained above and below the flat plate center section. Fringe patterns across the flat plate center section and fin in this area were very light and usable interferograms could not be photographed with the polaroid camera. In an attempt to improve on the fringe quality, polarizer plates were inserted in the reference beam between the mirror,  $M_4$ , and the hologram plate and in the scene beam between the lens,  $L_3$ , and the diffuser plate in order to ensure

polarization of both beams. No significant improvement could be noticed and they were subsequently removed. A one-quarter wave polarizer plate was then placed between the lens,  $L_1$  and the beam splitter in order to utilize circularly polarized light for the reference and scene beams. Okayama and Emori [14] found that their image resolution improved considerably; however, with this particular arrangement little to no improvement in the fringe resolution was observed and the approach was abandoned.

The transverse mode selector was then varied from 2.0 mm. to 1.5 mm. and later to 1.0 mm. in an effort to improve the coherency length of the laser light and consequently the image resolution. Due to the decrease in output light intensity, up to six exposures were taken during a run with flow established. Image and fringe definition were not found to increase possibly due to model vibration which was not visible to the eye.

The model was rotated to  $45^\circ$  and  $67\frac{1}{2}^\circ$  and double exposure holograms were taken with a 2.5 mm. transverse mode selector. There were no observable fringe patterns in any portion of the test section. Consequently it was believed that supersonic flow was not established due to tunnel blockage caused by the shock wave from the model and by slight model vibrations in passing through the transonic range. In the transition to supersonic flow, the model leading edge would sometimes flex as much as  $0.2^\circ$  depending upon the transition time.

The test section walls were changed from the total plexiglas side walls shown in Figure 1(a) to the aluminum walls with the optical quality glass port holes (Figure 1(b)). The better quality glass would hopefully improve the viewing and the port holes made the model much more accessible. The metal strakes were also removed from the model since they appeared to have a minimal effect on the flow, were an interference optically,

DOCUMENT**

flow was established. The plate leading edge shock and fin shock appeared quite fuzzy and light. Due to oil from the tunnel supply reservoir mixing in the flow, a light oil smear pattern can be observed across the fin in Figure 26. During one run, which could not be duplicated, the model pitched up as flow was established but did not vibrate. The plate shock and Prandtl-Meyer waves, fin shock system, and tunnel Mach lines became very distinct and well defined as seen in Figure 27. The schematic of the Schlieren photographs in Figure 28 points out the cause for the various flow lines observed. The non-uniformity of the free stream caused by tunnel leakage can be easily seen. Consequently the experimental work was discontinued due to tunnel conditions and time considerations.

It was felt at this point that if the holographic interferogram taken of the clear plexiglas fin at  $0^\circ$  rotation angle could be reduced to useful data for the computer program then the holographic method would be to a certain extent verified even though the actual density field could not yet be determined.

In obtaining interferograms from the hologram, the reconstruction technique shown in Figure 15 was used. The plane of constant  $Z$  across the model to be reduced was chosen to be the forward most vertical grid line crossing the fin. It should be pointed out that in order to simplify the hologram alignment process, all four reduction planes across the model should have been scribed on the exterior grids. The three photographic points across the  $Z$  plane on the  $y'$  axis were, for convenience, chosen to be where horizontal exterior grid lines crossed the  $y'$  axis on the fin. Five interferogram photographs were taken at points A, B, and C as shown in Figure 29. Photographs 2 and 5 were taken using a Kodak Wratten Gelatin Filter N.D. 2.0 placed in the reconstruction beam in order to reduce the

beam intensity and increase the fringe definition. These two photographs were also used to provide a check on the consistency of the reduction process.

All five negatives were blown up on the photo enlarger in the dark room and the plate, fin, grid lines and fringes were traced out on a sheet of white paper as shown in Figures 30-34. It was very difficult to trace the fringes in the region of the fin tip and fin root due to the photographic resolution and the fin tip shadow. Also fringes were not visible in the region of the fin leading edge shock. Consequently, connecting the fringe in front of the fin to the correct fringe on the fin was a best guess effort. Typical of the problem was that fringe lines in two of the drawings were initially improperly connected across the fin leading edge shock. After being checked against the photograph negatives, the fringes were reconnected and the data taken correlated well with the data from other drawings. The fringes in the fin root area were extremely light in some photographs which made it quite difficult to determine their centerline crossing the  $y'$  axis. Another point of difficulty was determining the location of the top and bottom of the fin. An error in drawing here will have an effect later when the fringe locations are normalized with respect to the fin height.

Enlarged positives were then made from the negatives as shown in Figures 35-39 to see if the data accuracy could be improved by eliminating the difficulties of tracing the fringes in the dark room. This method also made it possible usually to reassess the assumed path of the fringe lines at a later time if the data did not appear to correlate properly. The same problems of locating the fringe lines in the region of the fin tip and of connecting the fringe lines across the fin shock are readily apparent in the figures.

To obtain the fringe change across the fin one of the straightest fringes in the free stream region which paralleled the majority of other free stream fringes was selected. A straight line was drawn through its centerline and extended to cross the  $y'$  axis. The other free stream reference lines were then drawn parallel to the first and adjusted so as to best follow the centerline of the selected fringe. This method actually averages the free stream conditions and is only valid if the free stream is essentially uniform. Since it was not possible to obtain in the photographs the free stream fringe pattern forward of the leading edge Prandtl-Meyer expansion for the lower fin region, the fringe reference lines in photo enlargements were drawn over the fringes just prior to the fin shock. In order to adjust them to free stream conditions their location was moved downward a distance equal to 1.1 times the average fringe interval for that photograph. The figure 1.1 was observed in all the enlarged photographs to be the approximate fringe change across the Prandtl-Meyer expansion. In the drawings (Figures 30-34), fringe reference lines for the lower fringes (generally  $y' \leq 4.8$ ) were initially aligned along the straightest portion of the fringe prior to intercepting the fin shock. By comparing the reference line location on the drawing with the fringe pattern in the photographic enlargements the reference line location and fringe change were adjusted by an appropriate portion or all of the 1.1 fringe change caused by the Prandtl-Meyer expansion. All of the reference lines were then corrected for the tunnel wall and grid plastic parallax shown in Figure 19 and computed in Appendix B. The reference fringe locations were then normalized with respect to the wing height and the fringe numbers calculated by dividing the fringe change by the average fringe interval. For further details and calculations see Appendix A.

The data obtained for alignment points A and C by the two different reduction processes are plotted in Figures 40-43. The data obtained from the photo enlargements aligned at point C and shown in Figure 43 gave the best data agreement between two photographs. The worst data agreement was obtained from the reduction of the drawings aligned at the same point. The inconsistency in the data was probably caused by connecting the wrong fringe lines across the fin leading edge shock. The data fluctuations and discrepancies between the curves in the figures could have been caused by a number of things. It could have been caused, for instance, by not drawing the fringe reference line parallel to or exactly on the free stream fringe center line or slightly missing the fringe center as it crosses the  $y'$  axis or by misconnecting fringe lines across the fin shock as was illustrated in Figure 42. Fringe location errors could be caused by misdrawing the fin tip and root lines as was mentioned earlier. Another contributor would be measurement errors.

To analyze these sources for error, first consider that the typical fin size in the drawings and photo enlargements averaged about 2.5 inches high and 2.75 inches wide and that the fringe spacing averaged about 0.10 inches. All measurements were taken using a ruler graduated in 0.01 inches and readings were made to the nearest .005 inches. Since the average difference between the data points and curves ran around  $\frac{1}{2}$  fringe, some figures were calculated to determine what measurement errors could produce this fringe error. It was found that an error of .025 inches in alignment of the fringe reference line with the free stream fringe center line and/or fringe center line crossing the  $y'$  axis could produce  $\frac{1}{2}$  fringe error. This fringe error will also occur if the fringe reference line differs from the free stream center line by more than  $1.4^\circ$  when drawn 1 inch from the  $y'$  axis or by more than  $0.36^\circ$  when drawn 4 inches from the

y' axis. A difference of .01 inches in the average fringe interval could also produce a  $\frac{1}{4}$ -fringe error; however, this is not too likely since it is an average of fifteen to twenty-five intervals. By comparing the actual height-to-width ratio with those found in all the drawings and photo enlargements it was found that average error was around 2% or a distance of .02 on the y'-axis.

In order to compare the interferogram negative quality and the two different reduction techniques, a plot of the data for each negative was made as shown in Figures 44-48. Photographs 1 and 3 in Figures 44 and 46 gave the smoothest curves indicating the highest interferogram resolution. Photograph 5 (Figure 48) gave the worst dispersion indicating poor interferogram resolution; yet looking at the enlargement in Figure 39, the fringe line contrast is very good. In comparing Figures 40-48 it appears that the reduction technique using the photographic enlargements gave the most consistent data. This technique also provides a much easier and faster recheck on the proper tracing of fringe lines because it is extremely difficult and tedious to duplicate the fringe pattern to the same scale over the drawings using the photo-enlarger in the dark room.

All the data obtained by either method for one alignment point were then plotted in Figures 49 and 50 in order to observe the dispersion. A fringe number dispersion of about 0.6 fringes was observed in the data taken from the negatives aligned at point A and a dispersion of about 0.8 fringes for the data about point C. The dispersion is attributable to the inaccuracies in the drawings, to the photographic quality of the interferograms, and to the inaccuracies in correcting the lower fringe reference lines to free stream conditions. The last point is based upon the increased dispersion between the fin tip and fin root data.

Figures 51 and 52 show an integrated curve of the fringe change across the wing as determined by each reduction method. In constructing the curve, the data from the three aligned points was plotted so as to just overlap each other. These two curves were then compared in Figure 53. The maximum variation in the fringe number is about  $\frac{1}{2}$  a fringe but the variations in the location of the fringe maximums and minimums average about 0.1 inches on the fin. The location difference is probably due to improper drawing of the fringe reference lines compounded with not being able to measure the wing height accurately. Due to the inaccuracies introduced in tracing the negative and then reducing the data it is felt that the photo enlargement method is the more accurate reduction method.

With fringe data from only one field of view, the density field, obviously, could not be obtained. It was felt useful to consider the flow field axisymmetric in order to exercise the computer program and to provide a check on the program's ability to handle these particular curve shapes. Fringe data at 101 equidistant points across the fin from  $0 \leq Y' \leq 1.0$  was obtained from Figure 53 for both curves and fed in HOLOFER in Mode 3 for the axisymmetric case. For further details on HOLOFER see Appendix C. The scale factor,  $\alpha$ , in Equation 9 was then varied from 0.2 to 2.5 and a value to 1.0 was determined to yield the most accurate density solutions. This value was verified by feeding the function data,  $(\frac{\rho}{\rho_\infty} - 1)$ , calculated by Mode 3 back into the program in Mode 1 and comparing the fringe data calculated with the original fringe data obtained from Figure 53.

The density distribution for both the drawing and photographic reduction cases is plotted in Figure 54. The density as  $Y'$  approaches zero actually goes as the drawn lines even though the points indicate a dip.

Matulka [12, 13] pointed out that the computer program accuracy does not converge at the origin. The large variations of the density curves at values of  $Y' > 0.8$  are caused by the program trying to adapt to a step or shock wave type function at  $Y' = 1.0$ . If the remainder of the fringe data in Figure 53 for values of  $Y' > 1.0$  had been included as input data the density curves would have smoothed out. This shock wave step function effect was demonstrated and analyzed by Matulka [12, 13].

The low values of density for the photographic data curve around  $Y' = 0.38$  were unexpected but not surprising. First, the photographic fringe data curve is more extreme than the drawing fringe data curve and second, the density curves are not true values anyway since the field was considered axisymmetric and this is not the case in reality.

In general the density curves are felt to be reasonable under the assumed conditions. Consequently it is believed that the computer program could very easily and accurately handle a complete analysis of the flow field around the fin-flat plate.

In completing the analysis there are some data reduction problems which would have been encountered in reducing the interferograms at other model rotation angles which merit discussion. With no model rotation, adjusting the fringe reference lines close to the fin root to account for the leading edge Prandtl-Meyer expansion was relatively easy. However, when the model is rotated, the fringe shift across the Prandtl-Meyer expansion can no longer be considered a constant and it will be very difficult to adjust the fringe lines at lower values of  $Y'$  to free stream conditions. The best solution would be to increase the scene beam diameter and/or reduce the model size in order to photograph the free stream fringe lines forward of the plate leading edge. The free

stream lines could be connected to the appropriate fringe lines forward of the fin and this would eliminate the numerical correction and increase the fringe data accuracy.

Also at the rotated angles, fringe information will not be available for portions of the reduction plane due to shadows cast by the model sides as shown in Figure 55. In the lower portion of the hologram the fringe curve can be connected with a smooth line because the density field in that portion should be essentially constant. Care must be taken in completing the curve, though, since this information will be used in the integration of other rotation angles. The fringe curve in the upper portion must also be completed carefully but should be easier since the shadow will be smaller. For this particular model it was calculated that for angles greater than  $46.6^\circ$  the upper shadow would not penetrate the fin.

There are two more problems to be coped with which do not have apparent solutions at this time. The first has to do with the superimposing of fringe information from different locations onto one scene beam line as illustrated in Figure 56. In case I the superimposing of the fringe change in Region A onto that in Region C and locating the fringe reference line at point C' is tolerable because the density field in Region A should be fairly constant and uniform. However in case II where the fringe change in all three regions are superimposed and located at point C'', the answer is not readily apparent. If the plate and fin were of equal thicknesses then points A'' and C'' would be the same and the error would be somewhat reduced. If, in addition, the thicknesses were made as thin as structurally possible, the error would be reduced to a minimum. Also it might be possible to integrate the model geometry into the computer program but this has not been attempted.

With the model at rotation angles between  $0^\circ$  and  $90^\circ$  scene beam defraction at the fin root and tip areas would also present problems as seen in Figure 57. A minimization of the problem could again be achieved by minimizing the fin and plate thicknesses.

## VI. CONCLUSIONS AND RECOMMENDATIONS

The investigation, although not totally successful, has demonstrated the feasibility of using holographic interferometry to determine the flow field around a transparent model by looking through the model. The problems of model vibration and movement, of superimposing different fringe information on one beam, and of scene beam divergence through the fin root and tip regions must still be solved. The model vibrations and rotation to an angle of attack are attributable to the tunnel pressure fluctuations caused by tunnel leaks and to possible movement of the sting holder. It is felt that all three problems could be decreased to neglectable effects by reducing the overall model size and by incorporating the model geometry into the computer program.

The basic holographic arrangement was found to work quite well for this type of experiment. The holograms were generally high quality except when unfavorable tunnel flow conditions existed. The use of circularly polarized light recommended by Okayama and Emori [14] did not increase the hologram resolution appreciably but the method merits further considerations because of their excellent results.

The data reduction process was found to be the rate-controlling step in the investigation due to the time and labor involved. Reducing the data from enlarged photographs of the interferogram saved some time and appeared to increase the data accuracy. The data scatter of  $\pm 1/8$  fringe

was considered acceptable considering the fringe resolution in the holograms. It was felt that this could be reduced by using either a larger tunnel or a smaller model. With either of the changes it would be possible either to use the free stream fringe pattern forward of the model as the reference conditions across the whole model or to use a vertical fringe pattern, since the leading edge Prandtl-Meyer expansion and fin shock would not block out the free stream fringes above the fin. It appears that the use of vertical fringes would also considerably reduce the data reduction time.

With the use of Schlieren the flow network described by both Thomas [23, 24] and Winkelmann [26, 27] was verified to exist. From the top view ( $90^\circ$  model rotation) the fin shock and its fluctuations were observed and photographed through the flat plate plastic center section.

The computer program, HOLOFER, was found to be quite capable of handling the type of flow field fringe data which would be generated in a complete analysis of this type. As pointed out before it is believed that the program should be modified to incorporate the model geometry.

\* Locations to be corrected to free stream conditions

Table II. Tabulation of Fringe Shift Data Taken From the Photographic Enlargement of Photo 4

## APPENDIX A

### REDUCTION OF AN INTERFEROGRAM TO OBTAIN FRINGE SHIFT DATA

The fringe shift reduction process was accomplished using two techniques. The first involved projecting the interferogram negative onto a sheet of white paper using a photo-enlarger. The light fringes offered the best contrast and were therefore traced out in Figures 30-34. In each drawing it was necessary to begin tracing the fringes above the fin and work towards the fin root since the transition across the fin tip determined the correct connection of the fringes across the fin leading edge shock. In order to determine the fringe change, one fringe line in the free stream region forward of the fin which appeared the straightest and paralleled the majority of other fringe lines was selected. A straight line, called the fringe reference line, was drawn over its centerline and extended to cross the  $y'$  axis. The remaining reference lines were then drawn parallel to the first and along the centerlines of the remaining free stream fringes. In reducing the drawings it was not realized until later that the free stream fringe patterns before and after the plate leading edge Prandtl-Meyer expansion differed considerably. This effect was taken into account later.

A ruler scaled to 0.01 inches was then placed along the  $y'$  axis and the distances of the fringes and reference lines above and below the aligned  $y'$  plane were then recorded in Table I for Photograph 4. The fin width and length were then measured and the average values were recorded. The average fringe interval was determined by measuring the distance between the first and last fringes used and dividing by the number of intervals. The fringe change was found by subtracting the fringe crossing

point. The fringe number was calculated by dividing the change by the average fringe interval. The reference line location was then normalized with respect to the measured fin height. Since the actual fin height was very close to one inch, the above number was considered to be the number of inches above or below the aligned plane. Thus the table computing the tunnel wall and grid refraction displacements in Appendix B could be entered to determine the actual reference line location with respect to the aligned plane of the drawing (see Figure 29). The locations were then converted to the  $y'$  axis system by adding the normalized location of the aligned plane. After realizing that not all the reference lines were referenced to the free stream density forward of the plate leading edge, the enlarged photographs (Figures 35-39) were checked against the drawings. It was found that the Prandtl-Meyer expansion caused a fringe number change of approximately 1.1. Consequently each reference line in the drawing was compared with the enlarged photograph and an appropriate percentage of the 1.1 fringe number was used as a correction (see Table I). The calculated fringe numbers had the correction fringe number added to them while the  $y'$  locations were corrected by

$$y'_{\text{corr}} = y'_{\text{orig}} - \frac{(1.1 \text{ Fringe no.}) \times (\text{Fringe Interval})}{(\text{Fin Height})} \quad (\text{A-1})$$

The second reduction technique was to use enlarged photographs made from the interferogram negatives to obtain the fringe change. The fringe lines were first traced over lightly with a pencil and then verified against the other photographs to ensure correct tracing. A datum fringe reference line was chosen as before and drawn. The remaining reference lines for the upper free stream fringe lines forward of the Prandtl-Meyer expansion were then drawn parallel to the datum. When it became impossible

to use fringe lines forward of the expansion, the reference lines were then drawn along the centerline of the fringes between the expansion and the fin. The same ruler was used to obtain the fringe crossing points, the reference crossing points, fin measurements, and the average fringe interval and they were recorded in Table 2. The reference line crossing points were then corrected to free stream conditions, using a 1.1 Fringe number correction for those referenced to the pattern between the expansion and fin leading edge. The fringe number and reference fin locations were calculated as before. This method was considered more accurate because the reference lines and fringe lines could easily be rechecked for accuracy and corrected in the event that a fringe line was traced incorrectly or a reference line was misaligned. The accuracy was directly proportional to the hologram resolution which was not true for the drawings since the reference lines are drawn parallel to hand-drawn fringe lines.

## APPENDIX B

### CALCULATION OF TUNNEL WALL AND GRID PLASTIC REFRACTION CORRECTION

In the interferogram photographs used to obtain the fringe change, every point off the alignment axis will be slightly distorted due to the plastic tunnel wall and grid. This effect is illustrated in Figure 19. From Snells Law of Refraction, the angles of incidence and refraction are related by

$$\sin \alpha = n \sin \beta \quad (B-1)$$

where  $n$  is the index of refraction between plastic and air. Then can be written

$$\beta = \sin^{-1} \left( \frac{\sin \alpha}{n} \right) \quad (B-2)$$

Since the tunnel wall and grid have the same index of refraction, they can be considered on material with thickness  $t = ab$  in Figure 19. Then consider the height  $bd$  which can be written

$$bd = t \tan \alpha \quad (B-3)$$

The beam displacement,  $\Delta y$ , is then

$$\Delta y = bd - bc = t \tan \alpha - t \tan \beta \quad (B-4)$$

but  $\tan \alpha$  is

$$\tan \alpha = \frac{y_{\text{observed}}}{L} \quad (B-5)$$

Combining Equation (B-2), (B-4), and (B-5) the beam displacement becomes

$$\Delta y = t \left[ \frac{y_{\text{observed}}}{L} - \tan \left[ \sin^{-1} \left( \frac{\sin \alpha}{n} \right) \right] \right] \quad (B-6)$$

The true location of the observed point is then

$$y_{\text{true}} = y_{\text{observed}} - \Delta y \quad (B-7)$$

A FORTRAN computer program was written to generate a table giving the true locations versus the observed locations. In the program the constants and variables from the above equations were defined as

$Y_{\text{observed}}$	=	Y
$Y_{\text{true}}$	=	YTRUE
$\Delta Y$	=	DY
$\alpha$	=	ALFA
L	=	L
n	=	N

Since the computer cannot calculate Equations (B-2) and (B-6) as written, they were constructed by parts using such letters as AA, AB, etc. The program and tables are included in the next few pages.

## APPENDIX C

### APPLICATION OF COMPUTER PROGRAM "HOLOFER"

The computer program is an adptation of the inversion first proposed by C. D. Maldonado [ 9, 10, 11 ] and is designed to invert fringe numbers across a field to the density field. It can be operated in three different modes as described below:

#### (a) Mode 1

Mode 1 is utilized as a self-test of the computer program. It can either generate its own input density field using Subroutine FUNCT or read in a density field through Subroutine FREAD. The program then generates the fringe array and inverts the array back to the original density field. This mode was utilized in the present investigation to determine the value of the scale factor,  $\alpha$ , required to obtain the correct density across the fin.

#### (b) Mode 2

This mode reads in irregularly spaced fringe data and generates the fringe array at regular intervals across the field using Subroutine SHEET. By specifying NCODE = 1, the fringe array can be generated by one of the functions in Subroutine FUNCT. Mode 2 was not utilized.

#### (c) Mode 3

Mode 3 reads in the fringe data at regularly spaced intervals and inverts the array to density data across the field. The Subroutine GARRAY calls Subroutine READ to read in the fringe data. The first two cards preceeding the fringe data provide the program with the fringe field size, location, and symmetry.

The following parameters were used in considering the symmetric field case:

<u>PARAMETER</u>	<u>INPUT</u>
NOF	Run Number
IMAX	201
JMAX	1
ISYM	101
JSYM	1
IMS	2
JMS	100
Z	0.387
XO	0.0
YO	0.0
PHISYM	0.0

References [3] and [12] contain further details and applications of the computer program. A print-out of the program is included in the next few pages of this appendix.

```

*****HOLLOVERT*****
HOLLOVERT INVERTS THE FIELD AT AN ARRAY OF POINTS IN A VARIABLE
COORDINATE SYSTEM. IT SURVEYS NPTS POINTS EACH FOR A SET OF NLINS
LINES ACROSS THE FIELD.

SUBROUTINE GARRAY (G,GA,NOF,DGN,NUMB,XO,YO,PHISYM)
SUB000030

GARRAY FILLS THE DATA ARRAY OVER AN ORTHOGONAL AREA WITH THE REGULAR DATA OBTAINED BY THE METHOD CORRESPONDING TO THE PARTICULAR MODE:

MODE 1 - DATA OBTAINED BY SAMPLING A KNOWN FUNCTION SUPPLIED  
IN SUBROUTINE FUNCT AND SAMPLED IN SUBROUTINE GOLFF.

MODE 2 - DATA OBTAINED BY GENERATING A REGULAR ARRAY FROM  
IRREGULAR EXPERIMENTAL INPUT DATA READ IN. CALLS  
SUBROUTINE SHEET. (EXPERIMENTAL DATA MAY  
BE SIMULATED, SEE 'SHEET')

NAME 3 - UTILIZES RAW DATA TAKEN AT THE PROPER INTERVAL, OR PREVIOUSLY GENERATED, AND READ DIRECTLY INTO THE GARRAY. CALLS SUBROUTINE READ.

SUBROUTINE SHEET (G,D,XO,YO,PHISYM,NOF)
SHEET READS IRREGULARLY SPACED VALUES OF THE LINE INTEGRAL, AS
OBTAINED FROM HOLOGRAPHIC INTERFEROGRAMS. THE INTEGRAL LINES MAY BE
DEFINED EITHER BY GRID INTERCEPT POSITIONS, OR BY ANGLE AND RADIUS
ABOUT THE CENTER OF THE LABORATORY COORDINATE SYSTEM CENTER. LINES
MUST BE ENTERED IN CONSECUTIVE ORDER FROM LOWEST (NEG.) TO HIGHEST
(POS.) RADIUS. DATA MAY BE SIMULATED BY SPECIFYING NCODE=1,
FOLLOWED BY APERTURE POSITIONS FOR A FUNCTION NUMBER IN 'SUBFUNCT'.

MATHEMATICAL METHOD  
UPON FIRST ENTRY TO SPLIN, A CALL TO SPLICO IS MADE TO  
DETERMINE THE COEFFICIENTS TO BE USED IN PERFORMING THE  
INTERPOLATIONS. SEARCH FOR BRACKETING ABSCISSA VALUES IS  
ALWAYS MADE FROM THE REFERENCE LAST USED IN INTERPOLATING.

REFERENCE  
PENNINGTON, RALPH H., "INTRODUCTORY COMPUTER METHODS AND  
NUMERICAL ANALYSIS", THE MACMILLAN COMPANY, NEW YORK, 1965

MEAN AND STANDARD DEVIATION  
USAGE  
CALL GAUSS(IX,S,AM,V)  
DESCRIPTION OF PARAMETERS  
IX -IX MUST CONTAIN AN ODD INTEGER NUMBER WITH NINE OR  
LESS DIGITS ON THE FIRST ENTRY TO GAUSS. THEREAFTER  
IT WILL CONTAIN A UNIFORMLY DISTRIBUTED INTEGER RANDOM  
NUMBER GENERATED BY THE SUBROUTINE FOR USE ON THE NEXT  
ENTRY TO THE SUBROUTINE.  
S -THE DESIRED STANDARD DEVIATION OF THE NORMAL  
DISTRIBUTION.  
AM -THE DESIRED MEAN OF THE NORMAL DISTRIBUTION  
V -THE VALUE OF THE COMPUTED NORMAL VARIABLE

REMARKS  
THIS SUBROUTINE USES RANDU WHICH IS MACHINE SPECIFIC  
SUBROUTINES AND FUNCTION SUBPROGRAMS REQUIRED  
RANDU

METHOD  
USES 12 UNIFORM RANDOM NUMBERS TO COMPUTE NORMAL RANDOM  
NUMBERS BY CENTRAL LIMIT THEOREM. THE RESULT IS THEN  
ADJUSTED TO MATCH THE GIVEN MEAN AND STANDARD DEVIATION.  
THE UNIFORM RANDOM NUMBERS COMPUTED WITHIN THE SUBROUTINE  
ARE FOUND BY THE POWER RESIDUE METHOD.

USAGE			
CALL RANDU(IX,IY,YFL)			
DESCRIPTION OF PARAMETERS			
IX - FOR THE FIRST ENTRY THIS MUST CONTAIN ANY ODD INTEGER,			
NUMBER WITH NINE OR LESS DIGITS. AFTER THE FIRST ENTRY,			
IX SHOULD BE THE PREVIOUS VALUE OF IY COMPUTED BY THIS			
SUBROUTINE.			
IY - A RESULTANT INTEGER RANDOM NUMBER REQUIRED FOR THE NEXT			
ENTRY TO THIS SUBROUTINE. THE RANGE OF THIS NUMBER IS			
BETWEEN ZERO AND 2**31			
YFL- THE RESULTANT UNIFORMLY DISTRIBUTED, FLOATING POINT,			
RANDOM NUMBER IN THE RANGE 0 TO 1.0			
REMARKS			
THIS SUBROUTINE IS SPECIFIC TO SYSTEM/360 AND WILL PRODUCE			
2**29 TERMS BEFORE REPEATING. THE REFERENCE BELOW DISCUSSES			
SEEDS (65539 HERE), RUN PROBLEMS, AND PROBLEMS CONCERNING			
RANDOM DIGITS USING THIS GENERATION SCHEME. MACLAREN AND			
MARSAGLIA, JACM 12, P. 83-89, DISCUSS CONGRUENTIAL			
GENERATION METHODS, AND TESTS. THE USE OF TWO GENERATORS OF			
THE RANDU TYPE, ONE FILLING A TABLE AND ONE PICKING FROM THE			
TABLE, IS OF BENEFIT IN SOME CASES. 65549 HAS BEEN			
SUGGESTED AS A SEED WHICH HAS BETTER STATISTICAL PROPERTIES			
FOR HIGH ORDER BITS OF THE GENERATED SEQUENCE. IT SHOULD BE NOTED THAT			
SEEDS SHOULD BE CHOSEN IN ACCORDANCE WITH THE DISCUSSION			
GIVEN IN THE REFERENCE BELOW. ALSO, DESIRED AS ARE THE			
IF FLOATING POINT RANDOM NUMBERS ARE CHARACTERISTICS OF THE			
AVAILABLE FROM RANDU, THE RANDOM CHARACTERS IN FACT THESE			
FLOATING POINT DEVIATES ARE MODIFIED AND IN FACT TRAILING LOW			
DEVIATES HAVE HIGH PROBABILITY OF HAVING A TRAILING LOW			
ORDER ZERO BIT IN THEIR FRACTIONAL PART.			
SUBROUTINES AND FUNCTION SUBPROGRAMS REQUIRED			
NONE			
METHOD			
POWER RESIDUE METHOD DISCUSSED IN IBM MANUAL C20-8011,			
RANDOM NUMBER GENERATION AND TESTING
